Storm transposition

CEVE 543

2026-10-26

Summary

An event set is a long list of plausible storms with a probability attached to each. In this session we compute risk measures from an event set, build one for a watershed by moving observed storms around its region (stochastic storm transposition), weight storms that come with return periods, and see what a single rainfall number per storm leaves out.

- Average annual loss $\mathrm{AAL} = E[L]$, estimated by $\frac{1}{n}\sum_{i=1}^{n} L_i$ over n equally likely synthetic years, where L_i is the total loss in synthetic year i.
- VaR_α is the annual loss exceeded with probability $1-\alpha$; TVaR, also called CVaR or expected shortfall, is $E[L \mid L \geq \mathrm{VaR}_\alpha]$.
- From a ladder of design events (the 2- to 100-year storms, each with its damage d_k), AAL is the area under damage against annual exceedance probability $p_k = 1/T_k$, approximated with trapezoids: $\mathrm{AAL} \approx \sum_k (p_k - p_{k+1})\frac{d_k + d_{k+1}}{2}$.
- From a set of storms with no synthetic years, fit the distribution of an intensity measure, sort the storms from the rarest, $T_1 > T_2 > \cdots$, and weight each by its own rate $\lambda_j = 1/T_j - 1/T_{j-1}$ with $1/T_0 = 0$; then $\mathrm{AAL} = \sum_j \lambda_j d_j$.
- An intensity measure is one number per storm, and its frequency need not match the frequency of flooding or damage.
